KRAS Mutation as a Biomarker for Survival in Patients with Non-Small Cell Lung Cancer, A Meta-Analysis of 12 Randomized Trials

Min Ying¹, Xiao-Xia Zhu¹&*, Yang Zhao², Dian-He Li¹, Long-Hua Chen¹

Abstract

Background: Because there is no clear consensus for the prognostic implication of KRAS mutations in patients with non-small cell lung cancer (NSCLC), we conducted a meta-analysis based on 12 randomized trials to draw a more accurate conclusion. Materials and Methods: A systematic computer search of articles from inception to May 1, 2014 using the PubMed, EMBASE, and Cochrane databases was conducted. The enrollment of articles and extraction of data were independently performed by two authors. Results: Our analysis was based on the endpoints overall survival (OS) and progression-free survival (PFS). Nine records (All for OS, 7 for PFS) comprising 12 randomized trials were identified with 3701 patients who underwent a test for KRAS mutations. In the analysis of the pooled hazard ratios (HRs) for OS (HR: 1.39; 95% confidence interval [CI] 1.23–1.56) and PFS (HR: 1.33; 95% CI 1.17–1.51), we found that KRAS mutations are related to poor survival benefit for NSCLC. According to a subgroup analysis stratified by disease stage and line of therapy, the combined HRs for OS and PFS coincided with the finding that the presence of a KRAS mutation is a dismal prognostic factor. However, the prognostic role of KRAS mutations are not statistically significant in a subgroup analysis of patients treated with chemotherapy in combination with cetuximab based on the endpoints OS (P=0.414) and PFS (P=0.643). Conclusions: Our results indicate that KRAS mutations are associated with inferior survival benefits for NSCLC but not for those treated with chemotherapies integrating cetuximab.

Introduction

Although consistent progress has been made in diagnostic methods and treatment regimens, lung cancer remains the leading cause of cancer deaths worldwide with non-small cell lung cancer (NSCLC) accounting for approximately 85% of lung cancer patients (Ramalingam et al., 2011). Currently, many NSCLC patients present with an advanced stage at diagnosis, which may be partially due to non-typical early symptoms, lymphatic metastasis and hematogenous metastasis. Platinum-based cytotoxic chemotherapy, which was the standard therapy for advanced NSCLC has been considered to reach an efficacy plateau, whereas the targeted treatment of epidermal growth factor has provided a new insight for future personalized therapy treatment strategies (Carney, 2002). Until now, epidermal growth factor receptor (EGFR) mutation was identified to be a favorable predictive factor for EGFR tyrosine kinase inhibitor (TKI) treatment response (Usuda et al., 2014) but not a prognostic marker (NCCN, 2012), and EGFR-TKIs revealed encouraging efficacy, safety and survival for not only maintenance therapy but also second line therapy for advanced NSCLC (Qi et al., 2012; Alimujiang et al., 2013), which suggested avenues for future studies on the identification of additional potential biomarkers.

The KRAS oncogene is involved in tumorigenesis and encodes membrane-bound 21-kd proteins with an intrinsic guanosine triphosphatase (GTPase), which was noted for decades (Santos et al., 1984). Activation of KRAS proteins is triggered by extracellular stimuli, resulting in a switch from a guanosine diphosphate (GDP)-bound form of KRAS to a guanosine triphosphate (GTP)-bound form (Martin et al., 2013). The presence of a KRAS mutation in a wide variety of cancers (Chetty and Govender, 2013) was reported to be the most common molecular change in NSCLC, with an average mutation rate of 20-30% in adenocarcinoma and only rare mutations in squamous tumors, leading to the cascade activation of downstream effectors and cell proliferation (Roberts and Stinchcombe, 2014). In lung cancer, greater than 95% of KRAS mutations present in codons 12 and 13 (Riely et al., 2008).

Many clinical studies have attempted to determine a prognostic role for KRAS mutations; however, controversial conclusions persist because the first report indicated that a KRAS codon 12 point mutation was related...
to unfavorable prognosis based on the survival analysis of 69 patients with cancers ranging from stage I to stage IIIa (Slebos et al., 1990). While in another retrospective study on the implication of \( \text{KRAS} \) mutations, which was also analyzed in a cohort of patients with surgically resected early-stage NSCLC, \( \text{KRAS} \) mutation was a negative prognostic factor only for a stage II NSCLC subgroup but not the entire group comprising stage I and stage II NSCLC (Graziano et al., 1999). In addition, in the NCIC CTG BR 19 study, no statistically significant relationship was noted between \( \text{KRAS} \) mutation and disease-free survival (DFS) or overall survival (OS) for the patients with completely resected tumors (Goss et al., 2013). For advanced NSCLC, there is also no unequivocal conclusion. In a randomized trial investigating the efficacy of erlotinib as a maintenance treatment, which was reported by Brugger, \( \text{KRAS} \) mutation emerged as a significant poor prognostic factor for progression-free survival (PFS) in the placebo arm, revealing that \( \text{KRAS} \) mutation is related to unfavorable survival regardless of therapy (Brugger et al., 2011). Nevertheless, there are also studies that found that \( \text{KRAS} \) mutation is related to shorter survival for patients with advanced NSCLC (O’Byrne et al., 2011, Johnson et al., 2013). To resolve these differences, newer and larger meta-analyses are needed.

With regards to the most likely limited small sample sets and considerable heterogeneity among studies including different lines of treatment and enrollment of patient populations, we conducted an up-to-date meta-analysis based on 9 publications including patients from 12 randomized trials to fully assess the prognostic role of \( \text{KRAS} \) mutations in a group of NSCLC patients and further explore the implications of \( \text{KRAS} \) mutation in a specific subgroup of NSCLC patients.

Materials and Methods

Identification of eligible trials

After generating a search strategy, we performed a comprehensive systematic search in the PubMed, EMBASE and the Cochrane library databases from inception to May 1, 2014 using the following keywords: “non-small cell lung cancer,” “non-small cell lung carcinoma,” “non-small cell lung neoplasm,” “non-small cell lung tumor,” “non-small cell lung tumour,” “NSCLC,” “pulmonary adenocarcinoma,” “lung adenocarcinoma,” “adenocarcinoma of the lung,” “lung squamous carcinoma,” “pulmonary squamous carcinoma,” “squamous cell lung carcinoma,” “squamous carcinoma of the lung,” “\( \text{KRAS} \),” “\( k\)-ras,” “\( ki\)-ras,” “random” and “randomized”. Bibliographies from related meta-analyses or reviews were also searched. In addition, we also managed to contact corresponding authors for additional unpublished data. Abstracts or meeting proceedings were excluded.

Selection criteria

Acquired related citations in the form of abstracts were independently assessed by two authors according to the following exclusion criteria: (i) non-randomized trials and (ii) studies performed with NSCLC cell lines or animal models. Then, further screening of studies was performed with the following additional inclusion criteria: (i) trials that were published and written in English, (ii) randomized studies on the prognostic role of \( \text{KRAS} \) mutations in NSCLC patients without treatment restriction, and (iii) adequate data for estimating hazard ratios (HRs) and their 95% confidence intervals (CIs) for OS and PFS stratified by \( \text{KRAS} \) mutation status. Articles that could not be decisively excluded according to their abstracts were further assessed by searching for the full articles and corresponding supplementary data. With regards to studies with overlapping patient populations, the most recent investigation using updated data for publication was chosen for inclusion.

Data extraction

The following information was extracted based on the Preferred Reporting Items for Systematic Reviews and Meta-analyses statement (Liberati et al., 2009) from each recovered article: first author, year of publication, number of patients enrolled in the study, number of patients who were assessed for \( \text{KRAS} \) mutation status, median age, number of patients with a \( \text{KRAS} \) mutation, treatment regimen, primary endpoint, codon analyzed, demographic data (i.e., number of females, smoking history, stage of disease, and histology), and data linking \( \text{KRAS} \) mutation to treatment outcome (i.e., HR). Data extraction was conducted independently by two authors (MY and YZ) in accordance with a predefined information sheet. Discrepancies were discussed to reach consensus by including a third author.

Statistical analysis

For the purpose of analysis, the primary outcome was OS and the secondary outcome was PFS, which were expressed as a HR with 95% confidence interval (CI) for every treatment arm stratified by \( \text{KRAS} \) oncogene status. OS was defined as the duration of survival from randomization. PFS was determined as the time from randomization to progression, recurrence, or death from any cause or the last follow-up during the trial period, which was under the assumption that PFS may not be different from time to progression. When HRs comparing mutant with wildtype \( \text{KRAS} \) patients was not directly reported in a study, three independent investigators extracted basic survival data from the form of graphical curves using Engauge Digitizer version 4.1. Individual HRs and their variance in each treatment arm were reconstructed according to the method reported byTierney et al. (2007). If the HR indicated comparisons between wildtype and mutant \( \text{KRAS} \) patients, reciprocals of both the HR and its variance were extracted for approximate estimation. This HR estimates were then combined to give an overall HR. An observed, a HR above 1 indicated that poorer outcome was associated with \( \text{KRAS} \) mutation.

Heterogeneity was determined by the Chi-square and \( I^2 \) tests (\( I^2 <25\% \) no heterogeneity; \( I^2=25-50\% \) moderate heterogeneity; \( I^2>50\% \) substantial heterogeneity) (Higgins et al., 2003). All analyses were first conducted using the Mantel-Haenszel fixed mode (Mantel and Haenszel, 1959) based on the assumption of no extreme
KRAS Mutation as a Biomarker for Survival in Patients with Non-Small Cell Lung Cancer, A Meta-Analysis of 12 Randomized Trials

Results

Study selection and characteristics

A total of 637 potentially relevant articles were identified from three databases, and 403 articles were excluded for duplication as indicated in the flow chart of study selection (Figure 1). After screening titles and abstracts following the exclusion criteria, 92 articles were enrolled for further eligibility assessment, and 9 records (Schiller et al., 2001; Eberhard et al., 2005; Zhu et al., 2008; Douillard et al., 2010; Herbst et al., 2010; Khambata-Ford et al., 2010; Brugger et al., 2011; O’Byrne et al., 2011; Shepherd et al., 2013) were ultimately used in the meta-analysis. The characteristics of these 9 records are summarized in Table 1. Because the outcomes reported by Shepherd published in 2013 used individual data from 4 randomized trials including IALT (International Adjuvant Lung Cancer Trial), ANITA (Adjuvant Navelbine International Trialist Association), JBR.10 and Cancer and Leukemia Group B (CALGB) 9633, the final analysis covered data from patients from 12 randomized controlled trials in total. There were 10210 total NSCLC patients in all studies, and 3701 patients were available for testing for KRAS mutations with 695 patients (18.8%) harboring a mutation. Six studies (Eberhard et al., 2005; Schiller et al., 2001; Herbst et al., 2010; Khambata et al., 2010; O’Byrne et al., 2011; Shepherd et al., 2013) were performed in the first-line setting, and two (Zhu et al., 2008; Douillard et al., 2010) had second-line or higher treatment with one (Brugger et al., 2011) investigating maintenance treatment with erlotinib in nonprogressive patients after first-line platinum-based chemotherapy. All trials with the exception of two (Schiller et al., 2001; Shepherd et al., 2013) were conducted with advanced NSCLC patients. When stratifying by treatment regimen, chemotherapy was set as a treatment arm in five publications (Eberhard et al., 2005, Douillard et al., 2010, Khambata-Ford et al., 2010; O’Byrne et al., 2011; Shepherd et al., 2013), EGFR-TKIs in two articles (Zhu et al., 2008, Douillard et al., 2010) and the addition of cetuximab to chemotherapy in three articles (Herbst et al., 2010; Khambata-Ford et al., 2010; O’Byrne et al., 2011).

Association between KRAS mutations and survival benefit

All studies, including 646 patients with a KRAS mutation and 2699 patients with wildtype KRAS and the samples ranging from 39 to 780 patients per treatment arm, were used for OS analysis. Results from the pooled model indicated that significant poor survival benefit was associated with KRAS mutation in NSCLC patients (HR: 1.39; 95% CI: 1.23-1.56; P<0.001) (Figure 2A). No significant heterogeneity between the studies was noted (I²=33.9%; P=0.091). The 7 studies (Eberhard et al., 2005,

KRAS Mutation as a Biomarker for Survival in Patients with Non-Small Cell Lung Cancer, A Meta-Analysis of 12 Randomized Trials

Douillard et al., 2010, Herbst et al., 2010, Khambata-Ford et al., 2010, Brugger et al., 2011, O’Byrne et al., 2011, Shepherd et al., 2013) with relevant PFS data included 466 patients with a KRAS mutation and 1938 patients with wild-type KRAS. Pooled HR analysis (HR: 1.33; 95% CI: 1.17–1.51; \( P < 0.001 \); heterogeneity test \( I^2 = 49.6\%; P = 0.026 \)) indicated a consistent trend toward unfavorable PFS for patients with a KRAS mutation (Figure 2B).

Subgroup analyses according to disease stage, line of therapy, treatment, and point mutation

There were inadequate data for subsequent prespecified analyses for PFS for early stage patients. Following up on the available data, KRAS mutations were associated with poor survival not only for advanced NSCLC according to the pooled HR analysis for OS (HR: 1.50; 95% CI: 1.28–1.76; \( P < 0.001 \); heterogeneity test \( I^2 = 36\%; P = 0.102 \)) (Figure 3A) and PFS (HR: 1.42; 95% CI: 1.23–1.64; \( P = 0.026 \)) (Figure 3B) but also for early stage NSCLC based on the overall HR for OS (HR: 1.24; 95% CI: 1.03–1.50; \( P = 0.020 \); heterogeneity test \( I^2 = 4.2\%; P = 0.372 \)) (Table 2).

Subgroup analyses stratified by line of therapy (Figure 4) were restricted to 6 studies (Schiller et al., 2001, Eberhard et al., 2005; Herbst et al., 2010; Khambata-Ford et al., 2010; O’Byrne et al., 2011; Shepherd et al., 2013) for OS and 5 studies (Eberhard et al., 2005; Herbst et al., 2010; Khambata-Ford et al., 2010; O’Byrne et al., 2011; Shepherd et al., 2013) for PFS in which treatments were set for first-line therapy. Significant survival benefits were observed for KRAS wild-type NSCLCs in the OS analysis (HR: 1.30; 95% CI: 1.13–1.49; \( P < 0.001 \); heterogeneity test \( I^2 = 33.3\%; P = 0.133 \)) (Figure 4A) but not from the results of the PFS analysis (HR: 1.27; 95% CI: 0.99–1.64; \( P = 0.063 \); heterogeneity test \( I^2 = 52.4\%; P = 0.04 \)) (Figure 4C). However, the presence of a KRAS mutation was a poor prognostic factor for second- or later-line treatment according to the pooled analyses of HR for OS (HR: 1.94; 95% CI: 1.44–2.62; \( P < 0.001 \); heterogeneity test \( I^2 = 58.2\%; P = 0.082 \)) (Figure 4B) and PFS (HR: 1.60; 95% CI: 1.10–2.31; \( P = 0.013 \); heterogeneity test \( I^2 = 0\%; P = 0.653 \)) (Figure 4D).

Additional analyses assessing the role of KRAS mutations in the NSCLC subgroup treated with different combinations of therapy were performed by separately aggregating the studies according to chemotherapy,

**Discussion**

Although numerous experimental studies and clinical trials have been conducted over the years, the NSCLC prognosis remains dismal with 5-year overall survival rate of 10-15% and an even worse survival rate for advanced-stage patients (Siegel et al., 2012). The development of basic laboratory findings, genomics and genetic signatures may revolutionize future NSCLC treatment and provide novel insight into future targeted therapies based on the molecular characteristics of individual patient tumors (Schiller et al., 2013). Considering that few validated biomarkers are used to direct clinical treatment decisions, identifying more effective and less toxic treatments is of great importance for the selection of specific patients.

It is not surprising that the presence of a KRAS mutation is a potential biomarkers. In addition to clinical trials, the clinical implication of KRAS mutations was discussed in three meta-analyses (Huncharek et al., 1999; Mascaux et al., 2005; Meng et al., 2013), but there was no clear consensus. In the meta-analysis conducted by Huncharek et al., the magnitude of the effect of a KRAS mutation was combined with relative risk (RR), indicating a greater chance of death at 2 years from NSCLC, and the results (RR=2.35; 95% CI 1.61-3.22; heterogeneity test Q=15.52; P=0.03) revealed that KRAS mutation is related to shortened survival. The presence of a KRAS mutation was confirmed to be a poor prognostic factor (HR: 1.52; 95% CI 1.16-1.56; heterogeneity test P=0.01) using a random model, which may be true for only adenocarcinoma (HR: 1.52; 95% CI 1.30-1.78) based on a subset analysis assessing the expression of KRAS-p21 (21 kDa protein). When studies were stratified according to stage, a statistically significant impact of KRAS mutation on survival was noted for patients with stage I-IV disease but not those in early stages (stage I or stage I-III). In the latest meta-analysis...
focusing on the role of KRAS mutations (Meng et al., 2013). 41 articles were included ignoring the nature of studies with the publication year ranging from 1990 to 2012. KRAS mutation was suggested as a poor prognostic factor based on the summarized HR for OS (HR: 1.45; 95% CI 1.29-1.62; heterogeneity test $P_{	ext{het}}=42.9$%; $P=0.002$) using a random-effects model. Furthermore, similar results were observed in a subgroup analysis based on ethnicity in adenocarcinoma patients and patients harboring a KRAS codon 12 mutation, which strengthens the conclusion that KRAS mutation is a worse prognostic factor for patients with NSCLC. Nevertheless, the combined HRs (HR: 1.30; 95% CI 0.99-1.71; heterogeneity test $P_{	ext{het}}=55.3$%; $P=0.028$) for advanced-stage NSCLC indicate no relationship with survival, which differs from the results obtained for early stage patients (stage I or stage I-IIIa disease). As noted above, although the results confirmed that KRAS mutations indicated poor survival benefit in the overall analysis with significant heterogeneity, a discrepancy still exists in the subset analyses regarding disease stage.

Within the 9 articles used in our meta-analysis, the KRAS tumor mutational status was not associated with prognostic benefit for a certain homogeneous group of NSCLC patients according to 6 studies (Schiller et al., 2001; Douillard et al., 2010; Herbst et al., 2010; Khambata-Ford et al., 2010; O’Byrne et al., 2011; Shepherd et al., 2013). Only one study provided an indication of a lack of survival benefit for patients with KRAS mutations (Zhu et al., 2008). In addition, the association with poor survival benefit was only observed in the analysis of PFS ($P=0.020$), but it did not correspond with the OS results ($P=0.152$) in the study reported by Brugger et al. (2011). The study reported by Shepherd et al. (2013), including 4 randomized trials with 1543 patients, was in favor of the idea that KRAS oncogene status is not significantly prognostic for early stage NSCLC although subgroup analysis of patients with a KRAS codon 13 point mutation required more validation. In our meta-analysis based on the best evidence available from randomized trials, we found that KRAS mutation is a poor prognostic factor according to OS and PFS analyses. The poor prognostic role of KRAS mutation exists for early or advanced stage patients and patients treated with chemotherapy or EGFR-TKIs. However, the combine HR for the OS of early stage patients should be interpreted with caution because the results were not particularly overwhelming ($P=0.02$). When stratifying according to line of therapy, KRAS mutation is still related to poor survival with the exception of the subgroup of patients receiving the chemotherapy as a first-line therapy for the PFS endpoint. However, a trend toward statistical inferiority is noted for KRAS mutant patients ($P=0.06$). It is noteworthy that no significant relationship is observed for patients treated with chemotherapy coupled with cetuximab, which is a different scenario than that for colorectal cancer patients (Pirker, 2013). This discrepancy may be partially explained by the different pattern of mutational events and complexity of cell signaling pathways in the different tumors. Furthermore, the prognostic ability of KRAS mutations appears to be significantly stronger for OS than PFS based on our results.

To clarify the role of KRAS mutations in NSCLC, we summarized the updated randomized trials in which the KRAS oncogene was assessed according to survival data stratified by mutation status. However, some limitations remain. First, no additional data were acquired from the authors, resulting in the exclusion of some randomized trials due to inadequate data. Second, the exact HRs and 95% CIs were directly reported for several treatment arms, and some survival data had to be extracted from survival curves, which may be confounded system error and random error. Third, in some treatment arms, the number of KRAS mutant patients was relatively small (less than 20 patients), which increased the possibility of an imbalance in the baseline characteristics and bias within the study. Lastly, the assessment of adverse events is another important factor in making clinical treatment decisions. However, there were no sufficient data for performing analyses in detail to address such a concern.

As indicated above, the presence of a KRAS mutation is associated with poor prognosis for NSCLC, particularly for those with advanced stage disease or received second- or later-line therapy or treated with EGFT-TKIs but not for those treated with chemotherapy in combination with cetuximab.
